IVIE working papers offer in advance the results of economic research under way in order to encourage a discussion process before sending them to scientific journals for their final publication

* I would like to thank the remarks of an anonymous referee and Matilde Mas for this version. I would like to thank also the comments on a draft version from Barbara Fraumeni, Daniel Heymann and Utz Reich and the comments and support of my partners from the National Bureau of National Accounts in Argentina, specially Fernando Cerro (Director) and Federico Dorin, Luis Suárez and Marisa Wierny. This paper is a revision of a paper presented in the 27th General Conference IARIW 2002 which was won the Nancy Ruggles Prize 2002 and presented in a seminar in the OECD Canberra Group II-On the Measurement On Non-Financial Assets at Paris Meeting 2003.

** The author belongs to the National Bureau of National Accounts from Argentina since ten years. His main task is the estimation of the National and Regional Accounts (quarterly and annual series, input-output matrix, and capital stock) of the following sectors: Construction, Real State, Housing and Gross Investment.

ABSTRACT

This paper proposes to analyze the methodology of estimation of capital services in Argentina and its impact in the performance of the productivity growth during the 1990's. The capital stock is estimated according to the recommendations of the recent economic literature, mainly the OECD Capital Stock Manual; regarding how to use the hedonic valuation method (HV) to test the empirical depreciation of capital goods using a high desagregate data instead of the most known Perpetual Inventory Method (PIM) without empirical support. It is also presented a theoretical analysis about the methodological problems of both methods pointed out by the economic literature: the several assumptions in the PIM and the information problems regarding the use of traded used market prices in the HV case. The level of capital stock estimation is founded macroeconomic consistent with the principal national accounts aggregates. Taking into account the main recommendations of the OECD Productivity Manual and the OECD Capital Stock Manual, the paper reviews the proposals of estimation of capital services: efficiency-age profiles, level of aggregation, index number problem and the user cost approach in the context of their application of empirical estimation in Argentina. Given the relevance and dynamism of capital stock services for growth processes, an accurate measurement of this variable is critical. Thus, heterogeneity acquires more relevance, as well as the type of weights and the index numbers used to estimate its contribution to output. According to these results, evidences may indicate that during the nineties there was no productivity gain in the sense of Solow in Argentina. In any case, it may be inferred that the profile of economic growth was of the extensive type based on the accumulation of capital rather than disembodied technological progress or non-pecuniary spillovers.

KEY WORDS: capital stock, hedonic prices, capital services, productivity

RESUMEN

Este trabajo tiene por objeto presentar la metodología y principales resultados de una estimación exhaustiva de los servicios y valor del stock de capital de Argentina que el autor está llevando a cabo en la Dirección Nacional de Cuentas Nacionales de este país así como también se presenta el impacto de estas estimaciones en el análisis del crecimiento de la productividad de la economía argentina durante la década de 1990. El stock de capital es estimado de acuerdo a las recomendaciones de la literatura económica reciente, principalmente el reciente Manual de Stock de Capital de la OECD, en el sentido de utilizar el Método de Valuación Hedónica (HV), en lugar de los supuestos que implica el conocido Método de Inventario Permanente (PIM), con el objeto de testear empíricamente la depreciación y la vida útil media de los activos producidos tomando en cuenta información detallada y exhaustiva de más de cien tipologías de bienes de capital. Se analizan los problemas metodológicos de ambos métodos señalados por la teoría económica: los supuestos en el PIM y los problemas de información que surgen en el HV cuando se utilizan precios de transacción del mercado de bienes durables usados. El nivel del stock de capital estimado para Argentina resulta consistente con los principales agregados macroeconómicos. Con el objeto de estimar la productividad, este paper revisa los principales problemas metodológicos del proceso de estimación de los servicios de capital en el contexto del caso argentino, tomando en cuenta las principales recomendaciones del reciente Manual de Productividad de la OECD en cuanto a: perfiles etarios de eficiencia, nivel de agregación, números índices y costo de uso. Dada la relevancia y dinamismo de los servicios de capital en el contexto de la contabilidad del crecimiento de la economía argentina, la medición precisa de esta variable constituye un punto crucial. La evidencia empírica indicaría que para la economía argentina, las ganancias de productividad en el sentido de Solow fueron nulas durante la década de los noventa. Se podría inferir que el crecimiento de la economía argentina fue del tipo extensivo basado en la acumulación de capital más que en el progreso técnico desincorporado, rendimientos crecientes o externalidades no pecuniarias.

PALABRAS CLAVE: stock de capital, precios hedónicos, servicios de capital, productividad

“The measurement of capital is one of the nastiest jobs that economists have set to statisticians”

(J. Hicks, 1981) quoted by Ch. Hulten (1990)

1. Introduction

The present work is aimed at evaluating the contribution of capital stock to the productivity of the Argentine economy during the 1990's. Preliminary estimates of capital stock series currently under development according to the latest economic literature are used in this paper¹. Considering the recommendations in the latest economic literature about capital stock valuation and productivity measurements, changes occurred in Argentine economic growth during the nineties are assessed with a special emphasis on the behavior of the so-called '*Solow's residual*' or *total factor productivity (tfp)*'".

2. The Relevance of Capital Stock

The physical capital stock is the stock of capital goods of an economy, understanding such goods as those used as inputs to the production process i.e., those that entail the production of other goods, whose service life exceeds one year and are generally used by firms.

The relevance of this concept lies in the fact that it is the main component of wealth. Therefore, price variations in this type of assets involve significant wealth effects for their owners. Besides, the physical capital stock is one of the main production factors and its growth is significant not only because of its contribution to output but also because productivity growth and, therefore, long-term economic growth are mostly accounted for by its accumulation.

¹ This paper reports some preliminary estimates of capital stock in Argentina derived from partial results in a far-reaching project we are carrying out at the National Bureau of National Accounts in Argentina. The work as a whole, as well as the figures and conclusions should be understood as provisional. Only the author is to be held accountable for them.

3. Fundamental Concepts about Capital Stock

Although a detailed discussion of the different concepts involved in capital stock is not the purpose of this work, a brief description of them is provided below²:

- **Gross Capital Stock:** it is the stock resulting from the accumulation over time of consecutive investment flows (vintages) after subtracting retirements due to the end of their service life or economic obsolescence involving their replacement by a more efficient capital asset.
- **Productive Capital Stock:** it is the capital stock after deducting the foreseen losses of efficiency due to normal wear and tear. Capital services calculations are based on this concept.
- **Net Capital Stock:** it is the concept involved in stock as wealth, and results from valuing the productive capital taking into account the market age-price profile of capital goods.
- **Capital Services:** they are the flow of services –in physical terms– that the productive capital provides annually to output as a factor of production.
- **User Cost:** it is the price of capital services or the rental price corresponding to the use of a capital good as a means of production, either if the user is the owner or not.
- **Capital Services Value:** it is the quantity of services derived from capital goods valued at their notional or market user cost.

4. Classification and Coverage

According to the above definitions, capital stocks include all fixed goods repeatedly used in the production process in consecutive accounting periods³. The main

² For a detailed discussion, see OECD (2001) and Suárez (2000a).

³ See Chapter X, National Accounts Manual (National Accounts Manual, Chapter 10 (1993)).

aggregates included in this classification are: machinery and equipment; transport equipment; dwellings and non-residential buildings, additions and/or improvements; infrastructure; cultivated assets; and intangible assets such as software, etc⁴.

In this work an exhaustive estimation of capital stock has been prioritized over the time length of the series. The different groups of capital goods have been identified as uniformly as possible in order to emphasize a detailed statistical information and to obtain a capital stock estimate consistent both with the recommendations of current economic literature and with the high level of heterogeneity involved. Annex 1 details the capital goods included in these estimations, more than one hundred types according to available data:

- National Durable Equipment: 41 industries classified according to the five-digit index ISIC 3rd revision, considering the economic use matrix from National Accounts.
- Imported Durable Equipment: 52 types classified according to the five-digit ISIC 3rd revision, which results from aggregating individual capital goods classified according to the ten-digit Harmonized System for International Trade.
- Dwellings: single-person households, multiple-person households, urban and rural, including major replacement and alterations and shanties
- Non-Residential Private and Public Structures including buildings and their major replacement and alterations
- Livestock: cattle, sheep, goats, pigs and horses
- Agricultural Cultivated Assets: plantations, pastures, forestation, fencing, leveling and greenhouses.

⁴ It includes, besides, capital goods built or manufactured by the companies themselves (not purchased in the market), as well as the expenses incurred in extending the service life of existing capital assets, and the installation and intermediation costs needed to purchase new and second-hand equipment.

5. Estimation Methodologies – An Overview

There are two main methodologies available to estimate capital stock: the **Perpetual Inventory Method (PIM)** and the **Hedonic Valuation of Census, Survey or Administrative Record Data (HV)**.

5.1. *Perpetual Inventory Method (PIM)*

In order to estimate the productive capital stock and its services, the gross capital stock (less retirements or scrapping) should be first computed by accumulating investment series and discarding goods from stocks according to a retirement pattern that should reflect the behavior of the capital goods user sector, maintaining constant the productivity of goods that remain in the stock.

One of the shortcomings of the PIM is that it introduces a relatively high degree of uncertainty if the retirement or scrapping pattern of capital assets by user sector has not been determined.

In order to calculate the productive capital stock (less retirements and depreciations), goods still in stock should be depreciated after netting retirements, according to the foreseen reduction in efficiency determined by the normal economic cycle of that user sector. Thus, capital service flows might be estimated since, by assumption, they are proportional to the productive stock.

Selecting the efficiency, depreciation and service-life profiles by asset poses a similar problem. Many developing countries adopt retirement, efficiency and service-life profiles from developed countries. However, since the PIM reliability depends critically on these assumptions, profile selection should reflect the actual conditions of the country involved⁵; otherwise the capital stock level and variation will be biased⁶.

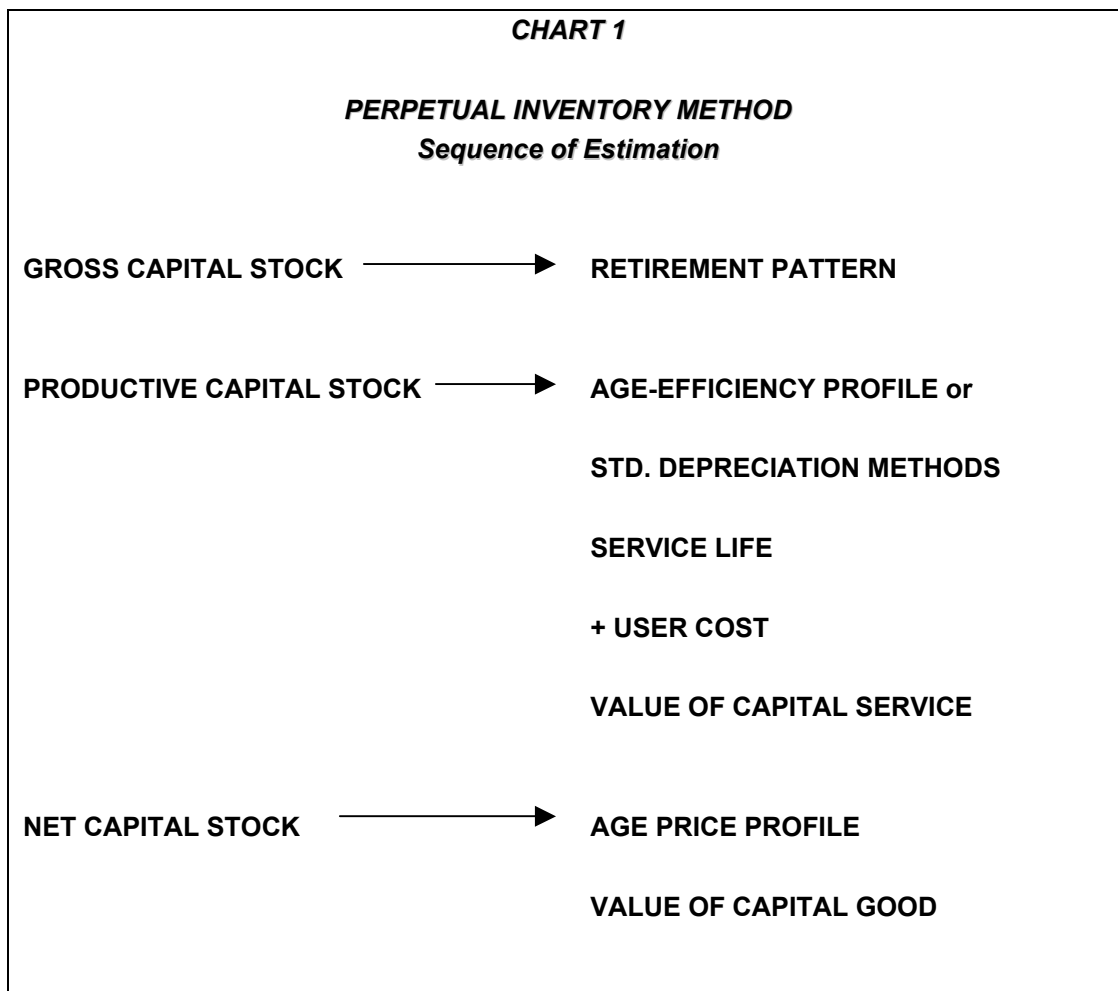

In order to obtain the net capital stock (or wealth capital stock), the productive capital stock should be valued according to the market price-age profile.

⁵ For example, the mortality functions which are widely used as retirement patterns become from 18 different types of curves developed by R. Winfrey, who derived his estimations from statistical data from the user industry in the United States for the 1920's and 1930's (!). Normal and lognormal functions or bell-shaped functions without empirical support are also used.

⁶ For a critical discussion of the PIM., see Miller (1983), (1990).

Consequently, the value of capital services according to age results from the combined effect of retirement or scrapping patterns, the age-efficiency and the age-price profiles. Generally, since detailed data about the age-efficiency and age-price profiles of fixed assets are inexistent, the PIM is limited to estimating the capital stock at constant prices as current prices, by applying standard depreciation methods to investment “*vintages*” as if they represented the actual age profile of services; in other words, as the net result of combining the retirement pattern, the age-efficiency profile and the age-price profile.

The following chart shows the impact of the several assumptions of the PIM in the process of estimation of every concepts of the capital stock:

Standard Depreciation Methods

Standard depreciation methods include the straight line, the geometric, and the hyperbolic method⁷. The two former methods generate convex age-efficiency profiles; the linear method involves constant depreciation amount with zero residual value at the end of service life. The geometric method involves constant depreciation rate with a positive residual value at the end of the asset's service life:

$$\text{Straight Line method: } D_t = \frac{V_0}{T}$$

$$\text{Geometric method: } V_t = V_0 [1 - (1/T)]^t$$

t: years 1, 2, ..., T (service life)

D: depreciation

V: value of the capital good

Less widely used though recommended in OECD (2001a), the sum-of-the-digits depreciation method involves a convex age-efficiency profile where depreciation amounts decrease linearly with age and the residual value is null at the end of the asset's service life:

$$\text{Sum-of-the-digits: } D_t = V_0 [T - t + 1] / [T(T + 1) / 2]$$

The United States Bureau of Economic Analysis (BEA) applies the geometric depreciation method to calculate capital stock adjusting it according to econometric studies that yield the depreciation curve implicit in market prices of capital goods, a function which is also affected by the actual retirement pattern⁸. The geometric depreciation pattern is adjusted by accelerating or delaying the decline of the asset value according to information provided in econometric regressions:

$$\text{Adjusted Geometric Method: } V_t = V_0 [1 - (R/T)]^t$$

⁷ For a detailed discussion of depreciation methods, see OECD (2001a), and Suárez (2000b).

⁸ See Fraumeni (1997), Katz and Herman (1997), BEA (1999), and Fraumeni and Herman (2000).

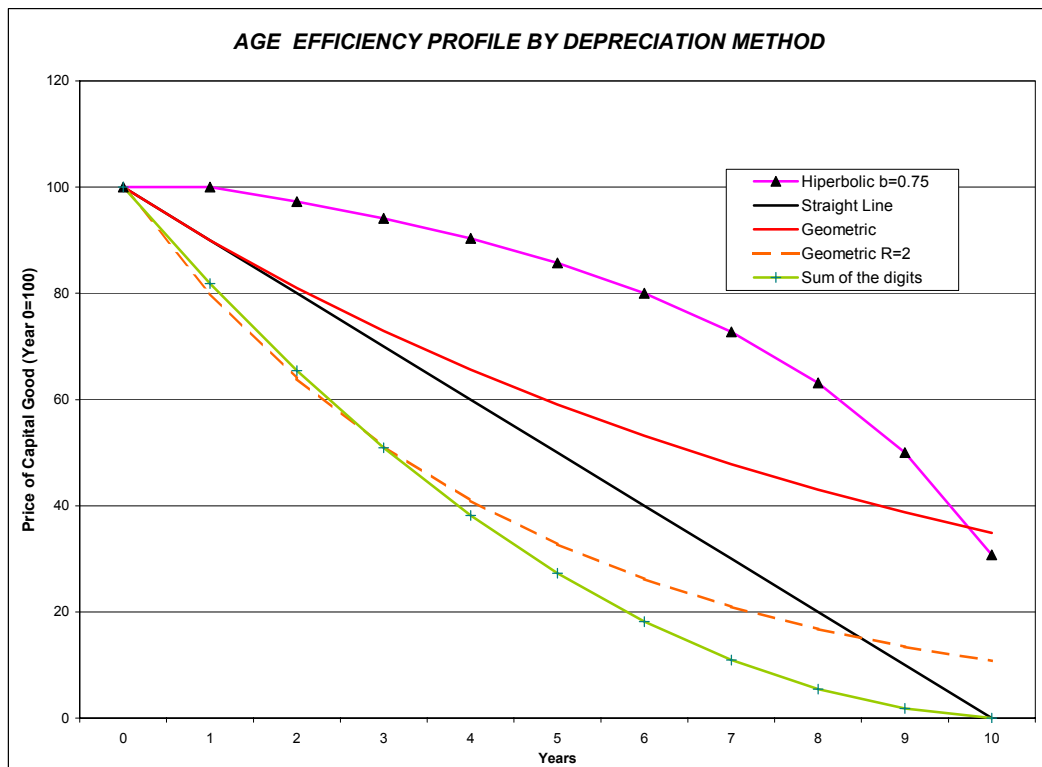

Where R is the coefficient that increases or decreases the efficiency profile according to market information. It should be noticed that, when R=2, this method coincides with the double-declining balance depreciation method.

The hyperbolic depreciation method is used by the United States Bureau of Labor Statistics (BLS) to compute capital services⁹ and by the Australian Bureau of Statistics (ABS), which also applies this function to estimate stock and fixed capital consumption. It generates a concave efficiency profile, i.e., the initial decrease in the productivity of the asset at the beginning of the age profile is more slowly than the above methods, efficiency falls at an increasing rate:

$$\text{Hyperbolic: } V_t = V_0 \left[\frac{T - (t-1)}{T - \beta(t-1)} \right]$$

Where β is a coefficient that adjusts the profile curvature according to the type of capital asset involved.

The following graph shows the impact of the standard depreciation methods in the age efficiency profile:

⁹ See for example Lysko (1995).

The rectangular depreciation method consists in maintaining the productivity constant over the asset service life until it undergoes, at the end of its service life, a single and sudden depreciation that exhausts its total initial value. In fact, thus estimated, capital stock coincides with the gross capital stock.

The geometric depreciation method is analytically advantageous because the productive capital stock equals the net capital stock, since only in this case the efficiency profile coincides with the price profile and, therefore, with the value profile of services¹⁰.

However, if the behavior of the age profile were actually geometric it may result from a combination of price profiles, efficiency profiles, and retirement patterns which are not necessarily geometric¹¹.

As noted by Hulten (1990) (1999), before making any assumption about the value profile of capital services, their curvature or decline pattern with age should be verified empirically in order to ascertain whether the assumed geometric pattern – however convenient it may seem from an analytical point of view– reflects the actual behavior of the market prices of used capital goods under study or its use in the production by user sector.

5.2. *Hedonic Valuation (HV)*

As noted earlier, some of the PIM's drawbacks are related with some assumptions about: the service life, retirement pattern, and non-neutral service flow profile for determining the capital stock. Hedonic valuation (HV) is intended to solve these problems but most recent economic literature encourages it, if and only if the necessary information in proper form is available: physical stock units and price profile broken down by age or vintage, model and other characteristics; extracted, if possible, from the same statistical source¹².

¹⁰ See Hulten (1990) (1999).

¹¹ If this argument is not taken into account, a fallacy of composition may result.

¹² See Hulten (1990), Jorgenson (1999), and Hill (2000) for a detailed discussion and review of the latest literature on the hedonic valuation of capital assets.

Taking into account the following attributes of the good: age and withdrawals, it would be feasible to test the empirical depreciation and the retirement pattern of the capital good.

Taking into account the attributes: model and vintage, the HV method should be applied to identify the quality change problem and the economic obsolescence problem.

It is important to note that in the case of the estimation of the capital stock in current prices term, the problem of quality change identification appears. According to the high heterogeneity of the capital goods, this problem has extremely importance. As pointed out by the National Accounts Manual, the quality changes should be included in the volume index, not in the prices.

The problem of how to identify the economic obsolescence has been discussed in the most recent economic literature. The unforeseen economic obsolescence in the capital goods, as a consequence of the rise of new goods with greater productivity or service life than the assets in the stock, may be verified by checking the decrease in the relative price of existing assets independent of the inflation and foreseen obsolescence. There is some support that this point is part of the quality change identification problem but other authors stress that it is part of the real holding gains.

The economic literature recommends that the measurement of the effect of the unforeseen economic obsolescence in the capital goods should be verified by the HV method.

Therefore the HV method acquire extremely importance in order to empirical analysis of the depreciation (and service life), retirement pattern, quality change and economic obsolescence of the capital goods in the firm, market, sector or country under analysis in order to avoid the several assumptions of the PIM.

In our interpretation the sequence for estimation the HV of capital stock might be the following:

1. Econometric estimation of the hedonic price indicator

$p_H=f$ (*attributes*), where the attributes depend on the intrinsic characteristic of the asset under study

2. Testing Functional Shapes of Depreciation

Applied first in this context by Hulten and Wycoff (1981a), the Box-Cox transformation; is a method that yields (besides the average service life), the depreciation function involved in market price series of capital goods. It is advisable to use this methodology to find the type of hedonic price function to be estimated econometrically in the previous step. These authors suggest that the influence of the retirement or scrapping pattern on the estimated depreciation curve should be taken into account in the valuation, as will be discussed below.

3. Testing the Functional Shape of the Withdrawals Function or Retirement Pattern using Survival Probability Approach (withdrawals by model and age)
4. Valuation of the physical stock with hedonic price and withdrawals vector according to its structure of attributes¹³
5. Computing the capital stock series valued through HV

If the available data about the physical stock come from census data, inter-censal acquisitions and withdrawals (stage3) should be computed. Acquisitions may be computed from investment series of the corresponding typology. Withdrawals may be derived from the depreciation curve found in stage 2 and the age structure of the disaggregated physical stock in stage 4.

According to the economic literature (Hulten and Wycoff (1981a), Fraumeni (1997) and Fraumeni and Hermann (2000), and others), HV Method has other problems too because of using the statistics of market price of transaction data for valuing a stock in place. These are:

- Asymmetric Information or Lemons Problem: Akerloff pointed out that the buyer usually has uncertainty about the real quality of the durable good because he suppose that the seller hide information about the real (lower) quality of the

¹³ Like the stratification method recommended by EUROSTAT (in its Handbook of Quarterly Accounts) and is applied in the case of Housing Sector also in Argentina (Coremberg (2000)).

good. This impact in an Overestimation of the Depreciation and an Underestimation of the value of the stock

- Censored Data Problem: the statistics of the transaction prices of used durable goods usually exclude retired models that are used in the stock in place. This impact in an Underestimation of the Depreciation and an Overestimation of the value of the stock. In order to correct this problem, Hulten and Wycoff (1981a) adjust the market price vector by the survival probability by model and by age taking into account the age structure of the stock.

The next table summarizes the HV problems:

Table 1. Some Problems of the Hedonic Valuation Method

	Depreciation	Stock Value
Asymmetric Information or Lemmon's Problem	<i>Overestimation</i>	<i>Underestimation</i>
Censored Data Problem	<i>Underestimation</i>	<i>Overestimation</i>

In my opinion, these HV problems or bias effects on the estimated value of the stock have lower magnitude than the bias problems from the assumptions from the PIM.

An alternative methodology of intermediate nature is the one used by the BEA, discussed above: an econometric estimation of the age-price profile and the retirement pattern in a base year and using the PIM with the previous findings till the next revision of the estimations.

6. Capital Stock Estimate in Argentina during the 1990's

6.1. Introduction

Several works may be quoted as the background for capital stock estimates in Argentina¹⁴. However, some relevant innovations are introduced herein:

- Coverage: estimations for more than one hundred different groups of capital goods have been performed^{15, 16}. It should be noted that this decision was a trade-off between coverage and the time-length of the series, since investment series with this desegregation level are available only since 1970 (except public investment series that began at 1900)
- Perpetual Inventory Method: this method was applied to the following series of:
 - Public investment in non-residential structures that include the public works at national, provincial and municipal level
 - Imported and national durable equipment (except transport equipment) recorded in the five-digit ISIC 3rd revision classification.

Hedonic Valuation Method: according to the suggestions discussed in section 5.2, this methodology was used for¹⁷

- Dwelling units (private and public, urban and rural)
- Private non-residential buildings

¹⁴ For other periods, the principal previous works are: Balboa and Fracchia (1959), Secretaría de Planificación (1991) and Hoffman (1991) which applied the PIM. For a complete bibliographic review, see also Coremberg (2001a).

¹⁵ Besides models by typology included in the estimate of automotive capital stock through HV.

¹⁶ See Annex 1.

¹⁷ At present, we are trying to estimate the stock of airplanes and ships by HV methodology-

- Transport equipment (freight trucks, buses, and automobiles used for productive activities)
- Livestock
- Cultivated Assets

The following subsection summarizes the application of the PIM to the Argentine case. Subsection 6.3 summarizes the application of the HV. The macroeconomic consistency of the estimated capital stock level is discussed in subsection 6.4. Finally, results are briefly analyzed as regards the average growth rate of net capital stock at constant prices per depreciation type.

6.2. The Perpetual Inventory Method applied to Capital Stock in Argentina

From historical evidences and information provided by qualified reporters from user sectors, it was concluded that in Argentina, in the average, assets are recalled from production at the end of their service life, independently of the user sector involved and the age-efficiency profile. This evidence confirms information from other undeveloped countries.

The types of capital stock computed by MIP mentioned above has been estimated at constant and current prices using various alternative depreciation methods: rectangular, linear, hyperbolic¹⁸, and adjusted geometric method¹⁹.

In every case, the service life declared by the BEA was used, properly adapted to Argentine conditions. The ISIC 3rd. revision five-digit classification was used. In the case of the adjusted geometric method, the balanced declination rates from BEA were also taken into account in order to guarantee methodological comparability with capital stock estimations from United States²⁰.

¹⁸ Similarly to the ABS and BLS, we suppose $\beta=0.5$ for the machinery and equipment types and $\beta=0.75$ for the public non-residential structures.

¹⁹ The adjusted geometric was applied taking into account the BEA coefficients. Results obtained by applying the sum-of-the-digits and double depreciation methods and others are similar to the results herein. They are available from the author on demand.

²⁰ See Annex 1.

6.3. *Hedonic Valuation of Capital Stock in Argentina*

In this section the adaptation of hedonic valuation to calculate the stock for the types of assets mentioned in subsection 6.1 is briefly discussed. Such assets constitute 64% of the value of the estimated capital stock for Argentina.

i. Dwellings

The dwelling series used in this work corresponds to the estimate of the Housing Property (dwelling services value), that represents about 9% of the Argentine GDP²¹. In this work, a brief summary of the estimation method is offered.

The detailed information from the National Census of Population and Houses 1991 is available (Censo Nacional de Población y Vivienda 1991 - CNPV'91), obtaining the number of dwellings units in 1991 separated by certain attributes: type, zone, size, quality, etc.

$$Q^v = A_i q^v$$

Q^v=dwellings stock opened by each *a_i* attribute considered, where *A_i* is the matrix representing the stock structure in terms of those attributes, and *q^v* is the number of censused dwellings

In order to value the corresponding stock, the hedonic price profile should be obtained, according to the attributes declared in the CNPV'91.

Since the information available from CNPV'91 does not provide data about prices, an econometric study of the hedonic price profile was performed resorting to the information provided in the National Survey of Household Expenses (Encuesta Nacional de Gasto de los Hogares 1996 - ENGH'96) about the rental value of surveyed houses and apartments. In order to correct the traded price problems noticed above, they were weighted by the survival probability implicit in the age structure of the census stock. The econometric estimation is based in the following functional form:

$$\log p_{alq}^v = \sum_{i=1}^n b_i a_i + u_i$$

²¹ For a detailed analysis of the dwelling stock, see Coremberg (2000), where the methodology and the estimates applied to change the base-year in National Accounts is discussed.

p_{alq} : dwelling rent price

b_i : parameters

a_i : attributes: age, size, quality, etc.

u_i : error of estimation

However, this econometric regression presupposes a semilogarithmic function. Thus, a test of functional shapes must be carried out in order to detect the implicit function that best relates rent prices with each of the attributes involved. In the case of age, depreciation type may be econometrically derived from this relationship.

In this case, a Box-Cox transformation similar to the one suggested in Hulten and Wykoff (1981) was applied. This type of econometric tool is useful for estimating both the parameters and the function: in the case of age, the average services life and the shape itself of the depreciation curve.

$$\boxed{p_{alq}^{*v} = \sum_{i=1}^n b_i a_i + u_i}, \quad \boxed{p_{alq}^{*v} = (p^{\theta_p} - 1) / \theta_p}, \quad \boxed{a_i^* = (a^{\theta_i} - 1) / \theta_i}$$

$$\theta = (\theta_p, \theta_i)$$

$I=1, \dots, n$ attributes, the first one is age

$\theta_{i,p} = (\theta_p, \theta_{i=edad}, \dots, \theta_n)$: parameters that determine the function that represents hedonic prices.

For example, if the restriction is $\theta = (0, 1, \dots)$, the relationship between price and age is represented by a semilogarithmic function: the age-price profile is convex and approximately geometric.

The econometric estimation yielded a hedonic model for rental prices, and the null hypothesis that the age-price profile is at least convex may be accepted. Later, this estimated rent was imputed to the remaining stock according to its characteristics. In other words, the dwellings grouped by the attributes considered in the CNPV'91 were multiplied by the vector of hedonic prices estimated from the data recorded in the EGH'96.

$$\boxed{\hat{p}_{alq}^v Q^v = \hat{p}_{alq}^v A_i q^v}$$

Finally, the user cost in terms of the ratio rent price/asset price was calculated by type and zone in order to transform the value of dwelling services into the stock value at market prices:

$$\frac{P_{alq}^v K^v}{P_{venta}^v K^v} = \mu_v$$

μ_v : user cost of the dwelling

The series of dwelling stocks at constant and current prices were obtained from recorded and non-recorded acquisitions calculated for the estimation of the value added of the construction sector²². Withdrawals were estimated considering the evolution of the age structure between CNPV'70, CNPV'80 and estimates for 1991²³.

ii. Non-Residential Private Structures

It is the other component of the real estate asset stock, representing the main fixed cost for private companies.

Stock was calculated as of 1993 considering the number of business premises by firm, zone and industry surveyed in the 1994 Economic Census (Censo Económico 1994 - CEN '94) and the implicit value of rents declared by jurisdiction and industry. The stock of non-residential building grouped by age at market prices was valued applying the estimated user cost for dwellings.

The series was constructed considering acquisitions and withdrawals that were calculated for the series of private non-residential buildings included in the construction value added²⁴.

²² For the methodology for the construction sector in the National Accounts of Argentina see Coremberg (1999).

²³ See Coremberg (2000).

²⁴ See Coremberg (2000).

*iii. Automobile Transport Equipment*²⁵

In order to value the number of vehicles which may be considered capital goods (vehicles for freight services and public transportation, small vans and automotive vehicles used by the enterprises) the following data were used: available administrative records for the year 2000 about the number of operating vehicles; official information (based on market information) about the price vector by trademark, model, and manufacturing year, as well as their corresponding attributes (horsepower, accelerating power, drive, weight, maximum speed, fuel consumption in liters).

Cross-section econometric estimations were performed in order to calculate the hedonic price index. Then a Box-Cox test was applied after weighting the traded used prices by its survival probability implicit in the age structure of the automobile stock, similar to the one described above for dwellings. Thus, the functional shape of the hedonic price profile was determined. The resulting age-price profile was approximately convex.

As an example, the automobile transport stock estimated through the PIM with the adjusted geometric method and the HV estimate were dissimilar considering their level but showed similar growth rates which partially validated the use of the BEA's adjustment for the geometric method²⁶.

It is outstanding to note that the HV valuation has been applied as a cross section valuation in a base year because of the lack of enough information to make a HV as panel data econometric estimation. Therefore the quality differences between the vintages and models of every type of good has been captured only in the base year of the valuation, but not the evolution of the quality change. As an outcome, the quality change is captured in the current price version of the capital stock but not in the constant price as recommends the National Accounts Manual²⁷.

²⁵ For the methodology of stock of automotive vehicles, see Coremberg (2001b).

²⁶ Whereas the PIM involved the accumulation of investment flows in the automotive industry considering the economic use coefficient, the HV involved a compatible valuation of detailed information about a stock of approximately 8,500 different models of vehicles.

²⁷ This subject will appear again in the next section 10 of this paper.

6.4. *Macroeconomic Consistency of Capital Stock Level Estimates in Argentina*

Considering the uncertainty derived from consecutive methodological decisions for determining the capital stock level in the PIM case, a macroeconomic consistency analysis should be performed so as to determine a level which is consistent with the remaining macroeconomic aggregates.

Theoretically, the capital stock value level should be consistent with the net operating surplus level in National Accounts (rK), so that the internal rate of return of the capital stock ($p_K K$) is at least equivalent to its opportunity cost that may be obtained by investing in alternative assets.

Taking into account a representative interest rate as a proxy of the opportunity cost of the capital, the internal rate of return of our estimation of the capital stock value should be at least 13.4% per year, which is the average value of proxy variable for the opportunity cost (average annual yield of the FRB Argentine bond) for the period 1990-2000.

$$\frac{rK}{p_K K} (iir_{ar}) \geq o.c._{ar} = 13,4\% \text{ annual}$$

$rK/p_K K$: net profitability of capital stock or internal rate of return

rK : profit amount generated by stock, it should be equal to the estimate of the net operating surplus in National Accounts

$p_K K$: capital stock at current prices

$o.c._{ar}$: internal rate of return that results from investing in an alternative asset that represents the opportunity cost of investing in Argentina (proxy variable: internal rate of return (iir) of the FRB bond \cong interest rate for foreign currency loans for 90-days unsecured commercial papers).

According to the first column of the table 2, this condition holds for the estimation of the capital stock for the period 1990-2000, independent of the depreciation method applied²⁸.

²⁸ The same is true for another source-the National Survey of Big Firms (Encuesta Nacional a Grandes Empresas - ENGE)-: net profits with respect to non-current assets declared by big firms amounted to 12% during the same period.

Table 2. Macroeconomic consistency of capital stock estimates in Argentina

1990-2000 Average	Internal Rate of Return (%)	K-Per- Cápita(u\$s)	K/GDP	Depreciation /GDP (%)	Net Investment /GDP (%)
Rectangular	12,2	21.572	2,68	10,1	5,6
Linear	15,5	16.878	2,09	10,6	6,5
Adj. Geom.	15,2	17.227	2,14	10,7	6,4
Hyperbolic	14,3	18.392	2,28	10,3	6,8

Source: Data worked out by the author, based on information from the DNCN and the IMF and the author's estimates of capital stock

From another perspective, if per-capita capital levels are a proxy variable for the country's wealth, as suggested by the convergence hypothesis of the economic growth theory²⁹, the per-capita capital level in developing countries like Argentina should be lower than that of developed countries like the United States, a situation which is verified by these estimations. Thus, for example, for 1998³⁰:

$$(K\text{-per cápita})_{USA} > (K/\text{per cápita})_{ARG}: \text{u}\$84.464 > \text{u}\$18.167$$

This inequality also holds for the capital-output relationship³¹ for the same year:

$$(K/Y)_{USA} > (K/Y)_{ARG}: 2,71 > 2,06$$

These relative levels between USA and Argentina capital stocks were maintained during the nineties decade.

The following table shows the capital output ratio for a set of countries that have official data for 1993, the base year of Argentine National Accounts. The second column presents this coefficient for the whole economy and the last one shows this ratio

²⁹ For a discussion of the convergence hypothesis, see for example Barro and Sala and Martin (1995).

³⁰ Argentina: Adj. Geometric Case. Although, for comparisons among different countries, this coefficient should be corrected by the PPP exchange rate, it should be noticed that, in Argentina, from 1991 throughout 2000 the rate of exchange between the American dollar and the domestic currency was 1\$ per dollar and a estimation for PPP exchange rate indicate an only 20% level of overvaluation of the domestic currency.

³¹ Argentina: Adj. Geometric Case. This coefficient is not affected by the above considerations since the numerator and denominator are both expressed in the same units. However, it should be noted that countries having higher capital-output coefficients are not necessarily wealthier than others: their relative productivity may be lower.

for the reproductive capital version, excluding the housing services sector for the output. In every case the estimation is at current prices:

Table 3. Capital Output Ratio

1993	Total	Reproductive
Argentina *	2.18	1.41
Alemania (R.F.A.)	2.62	1.45
Australia	2.68	1.92
Canada	n.d.	1.37
Chile	2.13	1.60
Dinamarca	3.39	2.04
España (Fundación BBVA)	2.44	1.60
Finlandia	3.21	2.31
Francia	2.34	1.09
Grecia	3.29	2.28
Italia	n.d.	3.74
Noruega	3.05	2.28
Reino Unido	2.58	1.71
USA (BEA)	2.77	1.88

*Adjusted Geometric Case-Source: Data worked out by the author, based on information from the IMF and UN

The capital output ratio for Argentina, in terms of the total and also in its reproductive version, is systematically lower than the group of DC's countries. If you take into account the economic growth theory, it is expected that the underdeveloped countries must have smaller ratios (or high level of capital productivity) than developed countries, according to the law of marginal decreasing productivity law.

Like the above macroeconomic relationships, depreciation and net investment seem relatively independent of the age-efficiency profile.

The incidence of depreciation on the GDP was approximately 10.5% in the average for the period 1990-2000³². It should be noted that, the fixed gross domestic investment for 1990-2000 represented 18.4% of the output; whereas net investment

³² The incidence of depreciation on the product is approximately similar to what has been discussed in the National Accounts Manual, UN (1993).

represented less than 50% of the gross investment, that is to say, net savings during the nineties represented approximately 6% of the GDP.

6.5. *Productive Capital Stock at Constant Prices by Type of Depreciation 1990-2000 - Some Preliminary Results*

This section discusses some results of the estimation for the productive capital stock at constant prices. It should be noted that, in every case, the HV estimation is applied to dwellings, private non-residential structures, and transport equipment, independent of the depreciation method used for the remaining stock, estimated through the PIM. Results obtained by applying the rectangular method are illustrative because they are equivalent to the gross capital stock. It should be recalled that the productive capital stock estimated through the geometric method is equivalent to the net capital stock, since age-efficiency and age-price profiles are coincident.

The following tables show the average growth rate of the aggregate stock for each subcomponent³³:

Table 4. Average growth rates of the Argentine capital stock

Period 1990-2000	Rectangular	Linear	Adj. Geom.	Hyperbolic
<i>Aggregate Capital Stock</i>	2.2%	3.1%	3.1%	2.9%
National Durable Equipment	-3.2%	-3.6%	-3.6%	-3.9%
Imported Durable Equipment	13.3%	16.5%	16.0%	15.6%
Total - Durable Equipment	0.5%	1.9%	1.6%	1.3%
Private Construction	4.3%	4.3%	4.3%	4.3%
Public Construction	1.8%	0.4%	1.0%	1.3%
Total Construction	3.0%	3.4%	3.5%	3.5%
Cultivated Assets	1.3%	1.3%	1.3%	1.3%

Source: Data worked out by the author, based on information from the DNCN and the author's estimates of capital stocks.

Except for the rectangular depreciation method, that yields results coincident with the gross stock at constant prices, the average growth rate of the aggregate

³³ The growth rates of every component is calculated taking into account a Laspeyres volume index (1993 base year).

productive capital is similar for all the depreciation methods analyzed. In the case of durable equipment, the aggregate result is also similar, even if data are broken down by origin. However, in the case of the hyperbolic method, the decrease in stock of national durable equipment is greater, because weights emphasize the corresponding investment flows since the efficiency loss due to aging is lower for this method. In every case, the highest growth corresponds to the stock of imported durable equipment.

It has been widely discussed whether investments in residential dwellings should be included in the gross capital formation and, therefore, in stock formation. The approach selected at National Accounts is that investments in residential dwellings should be included if users make them as market service producers. In other words, the capital stock includes rented dwellings and excludes dwellings used as such by their owners. However, since the incidence of rented dwellings on the total stock of dwellings is highly variable among different countries, for comparability reasons as regards different GDP's, the total services of dwellings are computed as a portion of the output and, therefore, their total amount is included in the stock, independently of tenancy.

Nevertheless, it is useful to analyze the data in the table above in terms of reproductive capital, excluding dwellings:

Table 5. Average growth rates of Argentine reproductive capital stock

Period 1990-2000	Rectangular	Linear	Adj.Geometric	Hyperbolic
<i>Reproductive Capital Stock</i>	<i>1.9%</i>	<i>3.3%</i>	<i>3.3%</i>	<i>3.1%</i>
National Durable Equipment	-3.2%	-3.6%	-3.6%	-3.9%
Imported Durable Equipment	13.3%	16.5%	16.0%	15.6%
Total – Durable Equipment	0.5%	1.9%	1.6%	1.3%
Non-Residential Structures	3.2%	4.2%	4.3%	4.3%
Cultivated Assets	1.3%	1.3%	1.3%	1.3%

Source: Author's estimates of capital stock

The exclusion of dwellings in the measurement of the stock does not affect the above conclusions. It may be added that the average growth rate of the reproductive capital stock is similar to the aggregated item.

The average share during the 1990-2000 period is also similar for all the depreciation methods considered herein:

Table 6. Structure of the Argentine capital stock by type of asset

1990-2000 Average	Rectangular	Linear	Adj. Geometric	Hyperbolic
Aggregate Capital Stock	100.0%	100.0%	100.0%	100.0%
National Durable Equipment	23.9%	13.4%	13.0%	15.0%
Imported Durable Equipment	7.2%	6.2%	5.7%	6.4%
Private Construction	46.6%	60.9%	59.7%	56.1%
Public Construction	20.9%	17.8%	19.9%	21.0%
Cultivated Assets	1.3%	1.7%	1.7%	1.5%

Changes in capital stock shares between 1990 and 2000 by type of asset also proved independent of the depreciation method. As an example, the following table for the adjusted geometric case is shown:

Table 7. Structure of the Argentine capital stock by type of asset

Adj. Geometric Case	1990	2000
National Durable Equipment	18.9%	9.2%
Imported Durable Equipment	2.6%	8.7%
Private Construction	55.7%	62.7%
Public Construction	21.9%	17.9%
Cultivated Assets	1.9%	1.6%

During the nineties the share of imported durable equipment tripled whereas by the end of this period, national durable equipment had decreased to half its share at the beginning of the decade. The higher dynamism shown by the private construction industry may be explained not only by the substitution of the public sector as generator of infrastructure works but also by the growth of non-residential buildings.

Therefore, growth rates and the structure itself of the productive stock at constant prices were relatively independent of the efficiency pattern applied. It should be added that the main conclusions of this section also hold for the productive capital stock at current prices.

7. Capital Services Contribution to Output Growth

When capital is analyzed as a production factor, its contribution to output growth must be measured by the service flows it generates.

From the point of view of a homogeneous asset, the standard depreciation methods discussed above enable an aggregation over time of different vintages of the same type of asset. Considering as the standard a unit of a new asset, the resulting adjusted stock amount declines with age insofar as its efficiency as a provider of service flows decreases.

Thus, the proportional change in the stock of the homogenous asset in question is equal to the proportional change in the services provided by the stock. the underlying assumption is that the ratio of service flows provided by stock over its amount remains constant for the same group of homogenous assets³⁴.

However, in order to determine the aggregate contribution of capital stock in terms of service flows, it is necessary to aggregate the services flows provided by heterogeneous capital goods.

In order to analyze the contribution of capital stock to the growth of the output from the point of view of growth accounting, three main questions should be taken into account: the type of index to be used for measuring capital services, which degree of aggregation should be selected, and which weights should be applied to different assets in the stock aggregate.

7.1. Index Numbers

Independently of the degree of disaggregation and the type of weight, different authors agree that both the growth of the output and productive factors should be measured through superlative physical volume indices, such as the Fisher's or Tornqvist's indices propounded in the economic theory.

In practice, for measuring productivity, the Tornqvist index is the most widely used because of its analytical advantages:

³⁴ See Hill (1999) (2000), Hulten (1990).

- It is a superlative index, i.e., an exact index in the sense of being derived from a flexible function.
- When the growth accounting approach is used for measuring productivity, standard assumptions are made (returns to scale, profit maximization, and perfect competition) consistent with an aggregate translog function of which the Cobb- Douglas function is a particular case. The Tornqvist index is the exact or superlative index for this type of functions.
- Unlike fixed Laspeyres-type weights, those used in the Tornqvist index are variable; hence its name of flexible aggregator³⁵. This is certainly advantageous because it removes the non-substitution bias involved in fixed weights of the Laspeyres type. In other words, the variation rates of the physical volume may be weighted applying current relative prices instead of those of the base-year, as in the Laspeyres approach.

However, it should be noted that:

- The translog shape of the aggregate function may result from the aggregation of production functions –either sectoral or individual– with a low elasticity of substitution, thus generalizing even further the approach followed in this paper.
- The type of aggregate function should be tested before deciding which index should be used. Otherwise, a methodological circularity may result.

The Tornqvist index may be represented as follows:

$$X^T = \prod_{i=1}^n (X_{i,t} / X_{i,t-1})^{1/2(v_{i,t} + v_{i,t-1})}$$

where v_i is the incidence, at current prices, of the value of subcomponent X_i on the total value of factor X .

³⁵ See Diewert (1976) (1978).

This index should be used for the output and for each production factor. It should be remarked that, in the case of capital, the use of the Tornqvist index results in a *flexible aggregation* of the different types of capital goods involved in the stock³⁶.

The Tornqvist index is a weighted geometric mean of the relative quantities, weighted by the arithmetic means of value ratios for both periods. Hence, its name of symmetrical index: it assigns the same weight to the two situations under comparison and, therefore, its value may be expected to be approximately the mean between the Laspeyres and the Paasche indices, as occurs in the case of the Fisher index³⁷.

The use of symmetrical indices is advisable only when the objective is to analyze productivity in a context of long-term trends in relative prices. However, since the series considered here are short in terms of time, the use of a symmetrical index might entail an economic deviation due to an unnecessary smoothing of changes in the structure of relative prices. Such effect might be further amplified if the logarithmic version of the index were used, as is commonly the case in most of the empirical literature about this subject. In order to avoid this effect and retain the variable weight characteristic, the Chain index was used in this paper: the variation rates at constant prices of the subgroups were weighted according to their incidence on the total value of the previous period, at current prices:

$$X^E = \sum_{i=1}^n (X_{i,t} / X_{i,t-1}) v_{i,t-1}$$

It may be remarked that this index retains the advantage of superlative indices when the series under study shows different relative price structures at the starting period and the final one, whereas price figures for intermediate periods are also intermediate³⁸.

³⁶ More generally, the Tornqvist index should be a flexible aggregator of capital goods classified by type and user sector. This is impossible in the Argentine case because basic data are inexistent, at least in the detailed and exhaustive form they are available from the point of view of supply.

³⁷ Besides, both the Tornqvist and the Fisher indexes satisfies the factor inversion test.

³⁸ See chapter XVI of the National Accounts System (UN (1993)).

7.2. *Aggregate vs Heterogeneous Approach*

Ceteris paribus the type of index and the weight, the contribution of capital to output growth may be measured as the growth of the aggregate stock weighted by the capital share in the output. Therefore, if a change occurs in the asset type-composition of capital stock, the growth rate of capital stock would be biased.

Measuring the contribution of capital stock to growth disregarding the heterogeneity of the goods involved implies the assumption that the contribution to output growth is the same for all capital goods. In fact, in relative terms, one "peso" invested in buildings has a lower average annual yield than a "peso" invested in machinery, mainly because the payback period for investments in machinery is shorter due to its lower relative durability.

Some authors suggest that discriminating between machinery and buildings in order to determine the capital contribution to growth involve adjusting data according to capital stock quality. The question remains unanswered because a less profitable investment –or, better, an investment with a longer payback period– does not necessarily imply a lower quality with respect to machinery. Besides, given the wide heterogeneity observed even within the group of machinery and equipment, an analysis with the greatest possible segregation is advisable.

7.3. *Weights – User Cost*

The weights to be used in the capital stock index should reflect the incidence of each asset value on the total, considering as such the capital value as asset, i.e., at purchase prices, or the incidence of that capital asset in terms of services.

As we have seen, the contribution of capital to output growth should be measured through an approximation to the value of capital services. Its quantity is proportional to the physical volume of capital stock, whereas the price of services is expressed by the user cost or the rental price of capital. In other words, the price paid for using a capital unit. When the firm demanding the capital asset is not its owner, the user cost is given by the market rental price. But when the demanding firm is the asset's owner, the user cost is a notional or imputed value.

Generally, the user cost may be represented by the following arbitrage condition:

$$\mu_{k,t} = p_{K,t} (r_t + d_t - \dot{p}_{K,t})$$

where

$\mu_{k,t}$: asset's user cost

$p_{K,t}$: price of the capital asset

r_t : financial cost of the invested capital

d_t : depreciation rate

The asset financing cost would be represented in this case by the first term above, $p_{K,t}(r_t+d_t)$:

$p_{K,t}r_t$: it is equal to the amount of interests if the asset were purchased through a loan; that is to say, it is equal to the opportunity cost if the purchase was made resorting to the company's funds.

$p_{K,t}d_t$: it is the depreciation cost or the asset's loss in value due to the fact that the expected average service life and/or the physical efficiency of the asset decreases with time.

The second term, $\dot{p}_{K,t}$ represents the nominal benefits resulting from the asset appreciation or revaluation due to price variations, independently of the age (theoretically, these variations are already reflected in $p_{K,t},d_t$), as a consequence of variations in the general price level or unforeseen obsolescence.

Three different approaches may be found in the literature regarding the method for measuring the user cost of capital assets:

- Depreciation Rate Approach: it was used by Ward (1976) and by Timmer (2000). According to this approach, the simplest way for estimating the user cost in terms of the ratio between the rental price and the asset price, by type is given by the depreciation rate: capital goods having a longer service life provide lower annual services.
- Ex-Ante Opportunity Cost Approach: it was first propounded by Jorgenson and Grilliches (1967), and later used by Timmer and van Ark (2000). It consists in estimating the user cost of each fixed asset as the sum of the following: an interest rate which represents the opportunity cost common to investments in every type of fixed assets, plus the depreciation rate by asset type, minus the

nominal appreciation or revaluation by asset type. Considering the available data, this approach has the following disadvantages:

- The interest rate should reflect the true weighted opportunity cost associated to investing in fixed assets, from the point of view of the user sector.
- In unstable economies, nominal price variations of capital goods (including real variations) tend to increase beyond the expected limits³⁹
- Ex-Post Residual Approach: according to Hall and Jorgenson (1967) and Jorgenson, Gollop and Fraumeni (1987), capital services may be calculated approximately by identifying them in the National Accounts System with the total income from capital ownership, as the difference between total output and labor income: gross operating surplus. By dividing this value into the capital stock, the implicit prices of capital services may be obtained⁴⁰.

8. The Growth of Capital Stock Services in Argentina during the 1990's

This section offers estimates of the growth of capital stock services in the Argentine economy during the nineties.

Calculations were performed as follows:

- a. Heterogeneous Approach: this approach was implemented taking into account detailed estimates of more than one hundred types of capital goods, both at constant and current prices. It should be noted that, if a detailed desegregation is available, the Chain index reflects changes in the relative prices of dissimilar assets and also changes in the relative prices of different relevant subaggegates: for example, public vs. private construction; national durable equipment vs. imported durable equipment; machinery vs. transport material or, even, changes

³⁹ For example, in inflationary economies, changes in relative prices may reach levels that result in negative user costs.

⁴⁰ In other words, the profitability of the capital stock (iir) is calculated (see section 6.4). It is constant for the user cost series in the case of Laspeyres 1993 index and varies every year in the Chain Index case.

in some capital stocks of specific use, such as those used in agriculture and livestock (tractors, other agricultural machinery, cultivated assets).

- b. Index Numbers: the variation rates of capital stocks corresponding to homogeneous types at constant prices were aggregated using the Chain index.
- c. Asset Value Weights: weights were calculated taking into account estimates at current prices for each of the stocks at market prices in order to compare these data with those obtained from applying user costs weights.
- d. User Cost Weights: in order to determine the aggregate index of capital services, the Ex-Ante methodology was applied to calculate the annual user cost⁴¹, except in the case of typologies integrating the construction stock, where a series of user cost worked out by the author was used.

Therefore, the rates of variation of capital services result in the following Chain index in the case of weights based on the asset value or the market price of capital assets, p_K ⁴²:

$$\dot{K}_{K,t}^E = \sum_{i=1}^{109} \left(p_{K_{i,0}} K_{i,t} / p_{K_{i,0}} K_{i,t-1} \right) v_{i,t-1}^K$$

$$v_{i,t-1}^K = \frac{p_{K_{i,t-1}} K_{i,t-1}}{\sum_{i=1}^{109} p_{K_{i,t-1}} K_{i,t-1}}$$

$i = 1, \dots, 109$ types of capital assets

Whereas, in the case of weights based on the user cost or equivalent rental price μ_k , the following relationship holds:

⁴¹ The interest rate used as proxy for the opportunity cost of capital is the interest rate for loans in foreign currencies associated with unsecured commercial papers due in 90 days published by the Central Bank of Argentina.

⁴² It should be noted that this index involves calculating the growth of aggregate capital stock as a weighted sum of the growth rates (at constant prices) of the 109 types of capital stocks, according to the structure of relative prices in the previous period. It should also be noted that, generally, estimates at constant prices of macroeconomic and sectoral aggregates in Argentine National Accounts are extrapolations of the respective levels at the base-year calculated with the Laspeyres physical-volume indices. Estimates at current prices, instead, are obtained by indexing values at constant prices through price indices. This remark is very important since the estimates at constant prices in developed countries are usually based on deflating current values.

$$\dot{K}_{k,t}^E = \sum_{i=1}^{109} \left(\mu_{k_{i,0}} K_{i,t} / \mu_{k_{i,0}} K_{i,t-1} \right)_{i,t-1}^k$$

$$v_{i,t-1}^\mu = \frac{\mu_{k_{i,t-1}} K_{i,t-1}}{\sum_{i=1}^{109} \mu_{k_{i,t-1}} K_{i,t-1}}$$

Calculations were made taking into account former estimates of the productive capital stock at constant and current prices for each of the standard depreciation methods applied⁴³.

The following tables summarize the effects of the different adjustments applied to measurements in order to estimate the growth of capital services for each efficiency profile⁴⁴:

- a. Age-Efficiency Profile Effect: it is reflected in the difference between the series of gross capital stock and the series of productive capital stock (less depreciation).
- b. Substitution Effect: it is the difference between the Laspeyres index (involving fixed weights for the asset values)⁴⁵ and a Chain index (involving variable weights).
- c. Weight-Change Effect: it results from the difference between two Chain indices of variable base: the previous index with weights based on the asset value, and an index with weights based on user cost estimates.

⁴³ Tornqvist-type indices yield results similar to those of the Chain indices reported herein.

⁴⁴ For a similar approach, see OECD (2001b).

⁴⁵ In this case, the base-year 1993.

Table 8. Average growth rates of capital stock services in Argentina during the 1990's

AGGREGATE CAPITAL STOCK	Rectangular	Linear	Adj. Geom.	Hyperbolic
Gross Capital Stock	2.23%	2.23%	2.23%	2.23%
<i>Age-Efficiency Profile Effect</i>	0.00%	1.01%	0.97%	0.89%
Productive Capital Stock	2.23%	3.24%	3.20%	3.12%
<i>Substitution Effect</i>	-0.10%	-0.05%	-0.04%	-0.05%
Chain Index - aggregation by market prices	2.13%	3.19%	3.15%	3.07%
<i>Weight Change Effect</i>	-0.07%	0.13%	0.10%	-0.11%
Chain Index – aggregation by user costs	2.06%	3.32%	3.26%	2.96%

REPRODUCTIVE CAPITAL Stock	Rectangular	Linear	Adj. Geom.	Hyperbolic
Gross Capital Stock	1.98%	1.98%	1.98%	1.98%
<i>Age-Efficiency Profile Effect</i>	0.00%	1.60%	1.51%	1.35%
Productive Capital Stock	1.98%	3.57%	3.49%	3.33%
<i>Substitution Effect</i>	-0.14%	-0.08%	-0.07%	-0.08%
Chain Index - aggregation by market prices	1.84%	3.50%	3.42%	3.25%
<i>Weight Change Effect</i>	-0.03%	0.18%	0.14%	-0.17%
Chain Index – aggregation by user costs	1.81%	3.68%	3.56%	3.08%

DURABLE EQUIPMENT STOCK	Rectangular	Linear	Adj. Geom.	Hyperbolic
Gross Capital Stock	0.61%	0.61%	0.61%	0.61%
<i>Age-Efficiency Profile Effect</i>	0.00%	1.86%	1.36%	1.18%
Productive Capital Stock	0.61%	2.47%	1.97%	1.79%
<i>Substitution Effect</i>	-0.32%	-0.20%	-0.23%	-0.21%
Chain Index - aggregation by market prices	0.29%	2.26%	1.73%	1.57%
<i>Weight Change Effect</i>	0.44%	0.95%	0.96%	0.27%
Chain Index – aggregation by user costs	0.73%	3.21%	2.70%	1.84%

CONSTRUCTION Stock	Rectangular	Linear	Adj. Geom.	Hyperbolic
Gross Capital Stock	2.68%	2.98%	2.98%	2.98%
<i>Age-Efficiency Profile Effect</i>	0.00%	0.46%	0.51%	0.52%
Productive Capital Stock	2.68%	3.43%	3.48%	3.49%
<i>Substitution Effect</i>	0.00%	0.00%	0.00%	0.00%
Chain Index - aggregation by market prices	2.67%	3.43%	3.48%	3.49%
<i>Weight Change Effect</i>	-0.01%	-0.02%	-0.02%	-0.01%
Chain Index – aggregation by user costs	2.66%	3.41%	3.46%	3.47%

The following conclusions may be derived:

- a. There are some obvious differences between the growth of gross capital stock and that of productive capital, as has been previously remarked.
- b. The difference between fixed and variable-base indices for the total capital stock is greater when weights are based on user costs, since durable equipment is weighted more favorable since they have had a shorter service life and yield therefore relatively higher annual services. Besides, durable equipment has gained incidence on the total stock of productive capital, as occurs in the case of imported durable equipment.
- c. The difference between the Chain Index and the Laspeyres Index is mainly due to aggregation by user costs, especially when durable equipment is analyzed separately, maybe because of a greater heterogeneity. Obviously, the substitution effect was weakly reflected because the length of the time series used were short.
- d. The effect is more noticeable when the durable equipment stock is analyzed separately.
- e. The sign of the substitutions effect is independent of the efficiency profile.
- f. The difference in growth rates resulting from weight changes between the rectangular and hyperbolic methods, and the linear and adjusted geometric method are due to the fact that the two former methods weight favorably national durable equipment, whose share decreased abruptly during this period.

9. The Contribution of Labor to Argentine Growth during the 1990's

For the sake of methodological consistency, an adjustment by the "quality" of labor was applied. We adopted the implicit differentiation approach⁴⁶: no explicit distinction of worker characteristics, but break down by sectors of activities and

⁴⁶ OECD(2001b).

occupational categories. We suppose that such differences in the relative wages by sector are correlated with the differences in labor qualification. Further research should be devoted to studying other differentiation features in the quality of labor: gender, age, and education.

In Argentina, available data about equivalent jobs and average remuneration by sector correspond to the one-digit ISIC 3rd revision classification broken down by occupational category: salaried and non-salaried workers (self-employed and unpaid family members). We take in account the official data published in DNCN (1999), that include an estimate of non-recorded employment for the period 1993-1997 and the author's estimate for the period 1998-2000, based on the same methodology.

For the sake of methodological consistency, a Chain index was used both for salaried labor (L_s) and non-salaried labor or mixed income (L_{ns}), in full accordance with the methodology applied to capital services:

$$\dot{L}_{s,t}^E = \sum_{i=A}^O \left(w_{s_{i,0}} L_{s_{i,t}} / w_{s_{i,0}} L_{s_{i,t-1}} \right) v_{i,t-1}^s;$$

$$v_{i,t-1}^s = \frac{w_{s_{i,t-1}} L_{s_{i,t-1}}}{\sum_{i=A}^O w_{s_{i,t-1}} L_{s_{i,t-1}}}$$

$$\dot{L}_{ns,t}^E = \sum_{i=A}^O \left(w_{ns_{i,0}} L_{ns_{i,t}} / w_{ns_{i,0}} L_{ns_{i,t-1}} \right) v_{i,t-1}^{ns};$$

$$v_{i,t-1}^{ns} = \frac{w_{ns_{i,t-1}} L_{ns_{i,t-1}}}{\sum_{i=A}^O w_{ns_{i,t-1}} L_{ns_{i,t-1}}}$$

$i = A, \dots, O$: sectors according to ISIC 3rd revision

These differences are similar in their magnitude to those determined for capital services:

Table 9. Average employment growth rates in Argentina

(1990-2000)	Salaried Labor	Non- Salaried Labor
Laspeyres Index	1.54%	2.04%
Chain Index	1.66%	1.94%
Substitution effect	0.11%	-0.10%

It should be noticed that in the case of non-salaried workers, a drop in the "quality" of labor occurred.

10. Growth Accounting in Argentina during the 1990's

The purpose of this section is to analyze the impact of alternative measurements of capital stock services on the accounting of growth in Argentina during the 1990's. More precisely, its purpose is to determine their impact on the so-called Solow's residual or *total factor productivity (TFP)*.

The approach of growth accounting assumes that technical progress or TFP is a residual that results from deducting the weighted growth of the factors of production from output growth. The underlying assumptions are: a) returns to scale, that is to say, the income from production factors exhausts the output; b) profit maximization: the relative price of each factor is equal to its marginal productivity, and c) the factorial contribution is measured by the effectively utilized capacity.

Thus, the following equation holds for growth accounting:

$$\dot{A}_t = \dot{Q}_t - s_K \dot{K}_{k,t} - s_{L_s} \dot{L}_{s,t} - s_{L_{ns}} \dot{L}_{ns}$$

A : Solow's residual or TFP

Q : GDP at constant prices

K_k : capital stock services

L_s : salaried labor

L_{ns} : non-salaried labor (or mixed income)

s_i : production factors' share in the output

Usual exercises are limited to measuring the growth rates of the output and the factors according to traditional physical-volume indices of the Laspeyres type. Even though adjustments may be made to reflect the quality of the factors, it is usually take the factor share in the total output as a constant. This implies an ex-ante assumption: that the aggregate output function of the economy belongs to the Cobb-Douglas type; besides the Laspeyres-type indices "freeze" the structure of relative prices at their base-year values.

Most recent literature on productivity measurements, especially OECD (2001b), recommends Chain indices both for the output and the factors and suggests that the measurement of the factors share should be made period-by-period⁴⁷. Hence, the equation representing growth accounting turns into:

$$\dot{A}_t^E = \dot{Q}_t^E - s_{K,t-1} \dot{K}_{k,t}^E - s_{Ls,t-1} \dot{L}_{a,t}^E - s_{Lns,t-1} \dot{L}_{ns,t}^E$$

The GDP Chain index was calculated by the following formula:

$$\dot{Q}_t^E = \sum_{i=A}^O \left(p_{i,0} Q_{i,0} / p_{i,t-1} Q_{i,t-1} \right) p_{i,t-1}^O, \quad v_{i,t-1}^O = \frac{p_{i,t-1} Q_{i,t-1}}{\sum_{i=A}^O p_{i,t-1} Q_{i,t-1}}$$

$i = A, \dots, O$: sectors, according to ISIC 3rd revision

$p_{i,t} q_{i,t}$: added value of the sectors integrating the GDP

The annual growth rates of the factors are those discussed above in sections 7 and 8, weighted according to their share at current prices in the previous period.

Several differences should be remarked with respect to other works of this kind:

- a. All the components of the TFP equation are calculated by applying Chain indices. The growth of production factors and the output itself are measured through a Chain index of the sub-aggregates involved. In the case of capital stock, 109 subgroups were weighted by their estimated user costs; in the case of salaried and non-salaried labor, hours worked opened by activity sector, as the output.
- b. The share of factors in the output varies from year to year. If it were constant, as in the case of *Kaldor's stylized facts* (1963), income distribution would be constant in an economic growth context in the long run. In Argentina, the income distribution suffered very important changes during the period under study:

⁴⁷ As in section 7.1, it may be said here that a Tornqvist-type index is usually recommended. However, it might entail economic variation because the period under study is very short. Anyway, the use of a Tornqvist index yields results similar to those obtained here through the Chain index.

Table 10. Functional Distribution of Income in Argentina

	1993	2000
GDP	100.0%	100.0%
Gross Operating Surplus	45.0%	50.9%
Salaried Labor	37.8%	31.0%
Non-Salaried Labor	17.1%	18.1%

Source: Author's estimates based on the DNCN

- c. The mixed income is considered as a separate factor of production, so its contribution to the growth of GDP may be inferred and discounted of the TFP.

Results derived from applying this methodology are summarized in the following table by efficiency pattern and index type:

Table 11. Growth accounting in the Argentine economy during the 1990's aggregate capital stock

LASPEYRES INDEX	Rectangular	Linear	Adj.Geom.	Hyperbolic
Q	2.28%	2.28%	2.28%	2.28%
K	2.30%	3.33%	3.22%	3.24%
Ls	1.76%	1.76%	1.76%	1.76%
Lns	2.33%	2.33%	2.33%	2.33%
Factorial Contrib.	2.13%	2.64%	2.59%	2.60%
K	1.14%	1.66%	1.61%	1.61%
Ls	0.58%	0.58%	0.58%	0.58%
Lns	0.40%	0.40%	0.40%	0.40%
TFP	0.15%	-0.36%	-0.31%	-0.32%
CHAIN INDEX	Rectangular	Linear	Adj.Geom.	Hyperbolic
Q	2.54%	2.54%	2.54%	2.54%
K	3.27%	3.38%	3.23%	3.27%
Ls	1.89%	1.89%	1.89%	1.89%
Lns	2.22%	2.22%	2.22%	2.22%
Factorial Contrib.	2.63%	2.69%	2.61%	2.63%
K	1.63%	1.68%	1.61%	1.63%
Ls	0.63%	0.63%	0.63%	0.63%
Lns	0.38%	0.38%	0.38%	0.38%
TFP	-0.09%	-0.14%	-0.07%	-0.09%

- a. The average growth of TFP in Argentina during this period was slightly negative measured in terms of Laspeyres-type indices⁴⁸. This type of fixed-base indices tend to bias TFP since they do not capture eventual substitution effects resulting from changes in sectoral and factorial relative prices.
- b. The TFP's negative trend decreases in the Chain index version, which also implies a factorial adjustment by "quality" since structural changes in the sectoral composition of the output and the factors are then detected.
- c. The growth of capital stock is the main factor contributing to economic growth. Therefore, an accurate measurement of this variable has a methodological and explanatory relevance⁴⁹.

Table 12
Importance of production factors in the economic growth of Argentina during the 1990's

	Laspeyres Index	Chain Index
K (Adj.Geom.)	70.37%	63.15%
Ls	18.07%	19.39%
Lns	22.76%	20.16%
TFP	-13.20%	-3.16%

- d. The above results are independent of the efficiency profile applied for measuring capital stock
- e. The differences in the factorial contributions between both index approaches are small. The small differences within every factor are compensated for opposite trends between factors. This would be because the quality change of the factors has not good enough captured by the implicit differentiation approach in the labor case and the HV approach in the capital case.

⁴⁸ It should be reminded that the rectangular version of capital stock corresponds to its gross version and, therefore, it overestimates its growth rate.

⁴⁹ Note that if we estimate the factorial contribution to growth fixing the functional distribution to the base year to every year of the series, we would underestimate the contribution of the capital to growth or overestimate the TFP.

Other attributes of labor that are not correlated to the sector would be relevant. In the case of capital, as we mentioned in section 6.3, the quality change of capital goods, because of the HV valuation as a cross section in a base year, is captured in the current price capital stock. This effect doesn't affect its contribution to the gdp growth (if is not in the capital stock growth, it is in the share of the capital in the gdp at current prices).

According to the considerations discussed in section 6.5 about classifying dwellings as capital good, a similar estimation was carried out for the reproductive capital stock⁵⁰:

Table 13. Growth accounting in the Argentine economy during the 1990's reproductive capital stock

<i>LASPEYRES INDEX</i>	Rectangular	Linear	Adj.Geom.	Hyperbolic
Q	2.27%	2.27%	2.27%	2.27%
K	2.10%	3.77%	3.57%	3.56%
Ls	1.76%	1.76%	1.76%	1.76%
Lns	2.33%	2.33%	2.33%	2.33%
Factorial Contrib.	2.02%	2.77%	2.68%	2.67%
K	0.94%	1.68%	1.59%	1.59%
Ls	0.64%	0.64%	0.64%	0.64%
Lns	0.44%	0.44%	0.44%	0.44%
TFP	0.26%	-0.49%	-0.40%	-0.39%
<i>CHAIN INDEX</i>	Rectangular	Linear	Adj.Geom.	Hyperbolic
Q	2.53%	2.53%	2.53%	2.53%
K	2.12%	3.81%	3.55%	3.58%
Ls	1.89%	1.89%	1.89%	1.89%
Lns	2.22%	2.22%	2.22%	2.22%
Factorial Contrib.	2.06%	2.81%	2.70%	2.71%
K	0.94%	1.70%	1.59%	1.60%
Ls	0.69%	0.69%	0.69%	0.69%
Lns	0.42%	0.42%	0.42%	0.42%
TFP	0.49%	-0.27%	-0.15%	-0.16%

The same conclusions hold in this case: rather than neutral technical progress in Solow sense, the accumulation process of (reproductive) capital accounts for the growth

⁵⁰ In spite of the exclusion of the housing sector from the gdp, the annual growth is very similar to the aggregate gdp for both methodologies.

of the Argentine economy during the nineties. This result are relatively independent of the depreciation method selected.

It should be noted that, since capital stock has not been adjusted by its degree of utilization, the residual might include its effects, resulting in a pro-cyclical behavior. Apart from estimation errors, other effects difficult to identify through this non-parametric methodology may be included in the residual non-constant returns to scale, spillovers, etc⁵¹.

It may be concluded that, during the nineties, Argentina would have an extensive-type economic growth⁵² based on the accumulation of capital rather than disembodied technological progress or non-pecuniary spillovers.

11. Conclusions

The contribution of capital stock to productivity In Argentina during the nineties has been analyzed by applying the economic theory of index numbers and the recommendations of the most recent economic literature about hedonic valuation of capital goods as an alternative of perpetual inventory method.

The level of capital stock estimation results consistent with the principal macroeconomic aggregates and its trends are relatively independent of the assumptions about depreciation methods.

The growth of the Solow's residual or TFP in Argentina was slightly negative for the 1990's. This trend tends to zero if measurements are made through Chain indices adjusted by the "quality" of production factors, even though only the reproductive capital stock is considered.

Given the relevance and dynamism of capital stock services for growth processes, an accurate measurement of this variable is critical. Thus, heterogeneity acquires more relevance, as well as the type of weights and the index numbers used to estimate its contribution to output.

⁵¹ For a discussion of this approach, see OECD (2001b) and Basu, Fernald and Shapiro (2001).

⁵² The conclusions of Timmer y Van Ark (2000) for Korea and Taiwan are similar.

The effects on the growth accounting of the flexibility aggregation of capital stock and salaried and non-salaried labor sub-aggregates has proved relatively neutral with respect to the efficiency profile used for estimating the capital stock.

According to these results, evidences may indicate that during the nineties there was no productivity gain in the sense of Solow in Argentina. In any case, it may be inferred that the profile of economic growth was of the extensive type based on the accumulation of capital rather than disembodied technological progress or non-pecuniary spillovers.
